## INTRODUCTION

On January 12, 1982 the occurrence of a duration magnitude 1.2  $M_d$  earthquake in north-central Arkansas heralded the beginning of an unusual swarm of over 30,000 earthquakes near the town of Enola, Arkansas. Although the cause of the earthquakes is as yet unknown, Johnston (1982) has suggested a reactivation of existing faults by the intrusion of a small magma body as one possible mechanism. Prior to 1982, the region had been relatively aseismic. Until the occurrence of the swarm, only six earthquakes were known to have occurred in the state of Arkansas (Coffman and von Hake, 1970; Jackson, 1979). Only one of these events--the  $m_{BLg} = 4.5$  Ferndale earthquake of January 1, 1969--was located in the vicinity of the swarm.

The Enola, Arkansas, region is located in the Arkoma Basin geologic province--locally known as the Arkansas Valley--north of the Ouachita orogenic belt and west of the Mississippi Embayment (Fig. 1). Locally, the basin contains approximately 4.7 km of sediments overlaying crystalline basement (Chiu *et al.*, 1984). The swarm occurred within this basement rock near the axis of the Menifee syncline and in the immediate vicinity of the Morrillton fault (Fig. 2)--a normal fault which, if extended to depth, would pass through the hypocentral region (Haar *et al.*, 1984).

The processed seismograms presented in this report were recorded by an array of portable digital seismographs deployed during a two and one-half week investigation conducted by the U.S. Geological Survey (USGS) at the request of the Tennessee Earthquake Information Center (Haar *et al.*, 1984). The largest earthquake recorded during this period was a magnitude 3.8  $M_d$  event that occurred on July 5, 1982, the last day of the investigation. Haar *et al.* (1982) give locations and source parameters for 53 earthquakes recorded by the array.

The known magnitudes of earthquakes studied in this report range from 1.1 to 3.8  $M_d$ . Such ground motions are not usually considered to have engineering significance. We believe, however, that such processed data can be of great value to the engineering community by providing a basis for better understanding the regional effects of magnitude scaling, distance attenuation, and local site conditions on engineering parameters of ground-motion.

The processing algorithms used in this study are consistent with those used in the routine processing of strong-motion accelerograms (e.g., Converse, 1984). Therefore, the currently processed ground motions are consistent in both form and quality with processed strong-motion data routinely distributed by the U.S. Geological Survey and the California Division of Mines and Geology for use by the engineering community. Ground motions provided in this report include "uncorrected" acceleration; SMA-1 simulated acceleration; "corrected" acceleration, velocity, and displacement; Fourier amplitude spectra; and five-percent damped pseudorelative velocity response spectra.

The discussion of each major processing step provides a brief description of the ground motions generated at that step as well as the algorithms used to produce those ground motions. Flowcharts summarizing these computational steps are provided in Figures 3 and 4.

## FIELD INVESTIGATION

On June 24, 1982, an array of 10 portable seismographs were deployed in a in the immediate vicinity of the earthquake swarm (Fig. 5). The purpose for the array was twofold: (1) to better define the location and size of the swarm, and (2) to determine source parameters for individual earthquakes. Recording systems consisted of velocity transducers or force balance accelerometers (FBAs) connected to Sprengnether DR-100 digital event recorders. The three FBA recording systems were placed in the center of the array and the seven velocity systems were placed along its perimeter. Shales and siltstones of the Atoka Formation (local bedrock) were less than 1 m below the surface at most of the velocity sites, and were probably no more than 2 to 4 m below the surface at the FBA sites (Haar et al., 1984). The transducers were buried approximately 0.5 m deep, where possible, to insure adequate coupling with the ground.

The recorders utilized a 12-bit analog-to-digital (A/D) converter, with a dynamic range and resolution of 72 db, to digitize the analog signals. Each system was set up to record three orthogonal components, two horizontal and one vertical, with each channel sampled at 200.32 samples per second and stored digitally on a magnetic tape cassette. The frequency response of the velocity recording system was flat from about 2 Hz to about 50 Hz, the cutoff frequency of the antialiasing filter. The frequency response of the FBA recording system was flat from about 0.1 or 0.2 Hz, depending on the predisposition of the amplifiers, to about 50 Hz, the natural frequency of the FBA transducer and the cutoff frequency of the antialiasing filter. Antialiasing was implemented with a 50 Hz low-pass, five-pole Butterworth filter. In Menlo Park, the data were transferred to a PDP 11/70 computer, demultiplexed into individual component files, and prepared for later analysis.

## UNCORRECTED TIME SERIES

The term "uncorrected" refers to the stage of processing whereby a strong-motion accelerogram is digitized and baseline corrected (Hudson, 1979). This stage is emulated in the present analysis by first preprocessing the FBA and velocity seismograms, then instrument correcting and differentiating the preprocessed velocity time series.

### *Preprocessing*

Preprocessing consisted of (1) identifying and removing traces dominated by noise, (2) removing transients, (3) performing a baseline correction, (4) tapering and padding the baseline-corrected time series, and (5) converting the amplitudes of the time series from internal storage units (counts) to ground-motion units.

Individual traces were excluded from analysis because: (1) they were dominated by noise as a result of a recorder malfunction or a visibly low

signal-to-noise ratio, (2) their amplitudes had exceeded the dynamic range of the system (clipped), or (3) there was no location, magnitude, or seismic moment available for the triggering event. Consequently, 573 velocity components and 60 acceleration components, representing 223 recordings from 49 events, were identified as suitable for processing (Tables 1-3, Fig. 6).

Transients appeared on the seismograms as either spikes or ramps. Spikes consisted of time marks or "glitches" that had not been removed during the original decoding process. They were removed with an interactive computer program developed by the second author. On some FBA traces, there was a transient that started in the P-wave train and lasted about one second. It was composed of a sudden shift in the baseline followed by a slow decay. This ramp was apparently caused by a power surge in the recorder when the cassette drive turned on (Fletcher *et al.*, 1981). It was removed from the horizontal traces by interactively replacing the early, low-amplitude portion of the recording with zeros. Unfortunately, this simple fix was not possible for the vertical traces.

Each trace was baseline corrected to remove any DC offset, after which a short cosine taper was applied to the end of each trace and zeros were added to bring the total number of samples to a power of two. This latter step was required by the Fast Fourier Transform (FFT) algorithm.

Amplitudes in terms of internal storage units (counts) were converted to ground-motion units using the algorithm:

$$A_g(t) = A_i(t) / (CC \cdot M \cdot DC) \quad (1)$$

where  $A_g(t)$  is the amplitude of the time series in ground-motion units ( $\text{cm/sec}^2$  for acceleration or  $\text{cm/sec}$  for velocity),  $A_i(t)$  is the amplitude in counts (where 2048 counts represents the full dynamic range of the system),  $CC$  is the coil constant of the transducer ( $\text{volts/cm/sec}^2$  for FBA transducers or  $\text{volts/cm/sec}$  for velocity transducers),  $M$  is the magnification of the system ( $M = 10^{G/20}$ ),  $G$  is the gain of the system in decibels, and  $DC$  is the digitization constant of the A/D converter in counts/volt.

#### ***Instrument-Corrected Velocity***

Preliminary analyses indicated that preprocessed velocity time series could be differentiated to simulate preprocessed acceleration. However, unlike the FBA transducer, the response of the velocity transducer is flat for frequencies exceeding 2 Hz. Therefore, in order to extend the frequency range of useable velocity data and to better simulate the FBA recording system, the preprocessed velocity time series were instrument corrected prior to differentiation using the algorithm:

$$S_v(f) = S_o(f) \cdot [1 - (f_i/f)^2 - 2i\beta f_i/f] \quad (2)$$

which assumes that the velocity transducer responds as a damped harmonic oscillator (i.e., a single-degree-of-freedom system) (Aki and Richards, 1980, p. 479). In the above expression,  $f$  is frequency in Hertz,  $S_v(f)$  is the FFT of the instrument-corrected velocity time series,  $S_o(f)$  is the FFT of the preprocessed velocity time series, and  $f_i$  and  $\beta$  are the undamped natural frequency and critical damping of the velocity transducer (Table 2).

In order to reduce the amplification of low-frequency noise, a high-pass Butterworth filter [Equation (7)] with a cutoff frequency of 0.17 Hz was applied to the velocity spectra prior to instrument correction. The value of the cutoff frequency was selected to be low enough so as not to filter out useable signal, yet high enough to prevent serious distortion of the instrument-corrected time series.

#### *Uncorrected Time Series*

The preprocessed acceleration and velocity time series developed during this stage of processing are referred to as "uncorrected" time series, since they have been subjected to about the same level of processing as a typical uncorrected strong-motion accelerogram (Hudson, 1979; Converse, 1984). As discussed above, uncorrected acceleration time series were also computed by differentiating preprocessed velocity time series. Differentiation was done in the frequency domain using the algorithm:

$$S_a(f) = 2\pi f \cdot S_v(f) \quad (3)$$

where  $S_a(f)$  is the FFT of the uncorrected acceleration time series and  $S_v(f)$  is the FFT of the instrument-corrected velocity time series. These differentiated velocity time series, together with the preprocessed acceleration time series described earlier, will be collectively referred to as uncorrected acceleration in the remainder of this report. Peak accelerations for these uncorrected time series are listed in Table 4.

#### SIMULATED SMA-1 TIME SERIES

The uncorrected acceleration time series described in the previous section were recorded on instruments whose high-frequency response characteristics are substantially different from that of a typical strong-motion accelerograph. As a result, it is not possible to directly compare the peak accelerations scaled from these time series with the existing catalog of strong-motion recordings. In order to produce a time series that can be used to estimate an instrumental peak from a typical strong-motion accelerogram, an algorithm was applied to each time series to analytically simulate the response of a strong-motion accelerograph. The algorithm used for this simulation is that given by Joyner (1984):

$$S_s(f) = S_a(f)/[1 - (f/f_i)^2 + 2i\beta f/f_i] \quad (4)$$

where  $S_s(f)$  is the FFT of the simulated accelerogram,  $S_a(f)$  is the FFT of the uncorrected acceleration time series, and  $f_i$  and  $\beta$  are the undamped natural frequency and critical damping of the hypothetical accelerograph. For this study, we used  $f_i = 25$  Hz and  $\beta = 0.6$ , nominal values for the natural frequency and damping of the SMA-1 strong-motion accelerograph (Hudson, 1979). Peak accelerations for these simulated accelerograms are listed in Table 4.

### CORRECTED TIME SERIES

The term "corrected" refers to the stage of processing whereby an uncorrected strong-motion accelerogram is instrument corrected, filtered, and integrated to produce velocity and displacement. A similar sequence of steps was used in the present study to compute corrected ground motions from the uncorrected times series described previously. Filtering was performed in the frequency domain using simulated bidirectional (zero phase) Butterworth filters. The major processing steps are discussed below.

#### *Identification of noise*

Low-frequency and high-frequency noise was identified by visual inspection of whole-record acceleration, velocity, and displacement spectra. Acceleration spectra were obtained directly from the uncorrected acceleration time series. Velocity spectra were obtained directly from the preprocessed, instrument-corrected velocity time series for velocity recordings, or from integrated uncorrected time series for FBA recordings. Displacement spectra were obtained by integrating the velocity spectra. Integration was done in the frequency domain using the algorithms:

$$S_v(f) = S_a(f)/2\pi f \quad (5)$$

$$S_d(f) = S_v(f)/2\pi f \quad (6)$$

where  $S_v(f)$  and  $S_d(f)$  are the FFTs of velocity and displacement, respectively. As a matter of convenience, the logarithms of the spectral amplitudes were plotted against both linear and logarithmic frequency. They are referred to as log-linear and log-log plots, respectively, in the discussion that follows.

The high-pass cutoff frequency (sometimes referred to as the corner frequency) was chosen to coincide with an abrupt change in slope in the low-frequency asymptote of the log-log acceleration, velocity, and displacement spectra. Experience with processing strong-motion accelerograms indicates

that such an abrupt change in slope is often associated with the onset of low-frequency noise. Emphasis was placed on the displacement spectra, since they were generally found to be independent of frequency at low frequencies, thereby making it easier to identify the onset of noise.

Inspection of the log-linear spectra indicated that the uncorrected time series were generally free of noise up to the 50 Hz limit imposed by the antialiasing filter. We did, however, apply a low-pass filter with a cutoff frequency of 57.5 Hz simply to insure adequate attenuation of high-frequency noise beyond the limit of the antialiasing filter.

### ***Filtering***

Frequency-domain, bidirectional (zero-phase) Butterworth filters were used to filter the uncorrected time series prior to instrument correction and integration. The frequency representation of these filters (Oppenheim and Schafer, 1975; Converse, 1984) is given by the following expressions:

$$H_h(f) = [1 + (f_h/f)^{2N}]^{-1} \quad (7)$$

$$H_l(f) = [1 + (f/f_l)^{2N}]^{-1} \quad (8)$$

where  $f_h$  is the high-pass cutoff frequency,  $f_l$  is the low-pass cutoff frequency, and  $N$  is the order of the filter.

The order of the low-pass filter ( $N = 8$ ) was chosen to simulate an FFT filter--a cosine taper with a bandwidth of 5 Hz--similar to that used in the routine processing of strong-motion accelerograms (Converse, 1984). The order of the high-pass filter ( $N = 8$ ) was chosen to simulate the high-pass, bidirectional Butterworth filter used in the routine processing of strong-motion accelerograms (Joyner, 1984).

In order to accommodate filter transients produced during the application of the high-pass filter, each time series was tapered and padded prior to filtering. Preliminary studies indicated that pads equal to 75 percent of the original duration of each time series were needed to accommodate the longest filter transients. As suggested by W.B. Joyner (personal communication, 1987), one of these pads was applied to the front and one was applied to the rear of each time series. If necessary, additional zeros were added to the rear of each time series to bring the total number of samples to a power of two.

### ***Instrument Correction***

The uncorrected acceleration time series derived from the FBA recordings did not require instrument correction, since the frequency response of the FBA

recording system was flat down to 0.1 or 0.2 Hz, well below the onset of low-frequency noise. The uncorrected velocity time series, however, were filtered (see above) then instrument-corrected prior to integration in order to extend the frequency range of useable velocity data. Instrument correction was performed with the algorithm given by Equation (2).

### **Corrected Time Series**

Different processes were used to compute "corrected" time series depending on whether the original time series was an FBA or velocity recording (Figs. 3 and 4). For FBA recordings, the corrected time series were computed from the uncorrected acceleration time series by: (1) tapering, padding, transforming into the frequency domain, filtering, transforming into the time domain, and unpadding to produce corrected acceleration, (2) integrating, baseline correcting, tapering, padding, transforming into the frequency domain, filtering, transforming into the time domain, and unpadding to produce corrected velocity, and (3) tapering and padding the corrected velocity time series, then integrating and unpadding to produce corrected displacement.

The baseline correction in step 2 was necessary because of a visible distortion (drift) in the baseline of the integrated acceleration time series that resulted from an apparent power-supply fluctuation in the feedback loop of the FBA transducers. Preliminary studies indicated that we could substantially reduce this drift, and thus reduce the amplitude of the resulting filter transients, by fitting a parabolic baseline to each integrated acceleration time series prior to filtering. Also, by integrating the acceleration time series before filtering in step 2, we avoided having to integrate the filter transients twice during the computation of corrected displacement.

For velocity recordings, the uncorrected velocity time series were tapered, padded, transformed into the frequency domain, filtered, and (1) differentiated, transformed into the time domain, and unpadded to produce corrected acceleration, (2) transformed into the time domain and unpadded to produce corrected velocity, and (3) transformed into the time domain, integrated, and unpadded to produce corrected displacement.

Some of the vertical components of the FBA recordings contained significant transients in the first few seconds of the corrected velocity and displacement time series as a result of integrating the ramps caused by the start-up of the tape drive during recording. When this occurred, the high-pass cutoff frequency was increased until the transient was reduced to an acceptable level. In some cases, however, these transients are still somewhat visible, especially in the displacement time series.

Peak values scaled from corrected time series, together with the corresponding high-pass cutoff frequency used in their development, are listed in Table 4. Selected plots are displayed in the *Appendix*. Because of the large number of time series processed in this report, it is not feasible to present plots for every one of them. Therefore, the *Appendix* contains plots for only those events with  $M_d \geq 2.0$ .

## FOURIER AND RESPONSE SPECTRA

The Fourier amplitude spectra of the corrected acceleration time series were computed for the standard 91 periods used in the routine processing of strong-motion accelerograms. The algorithms used to make these calculations are similar to the PHASE III processing algorithms provided in AGRAM (Converse, 1984).

The corrected acceleration time series were also used to compute response spectra for the standard 91 periods using computer algorithms developed by Nigam and Jennings (1969). It is customary in such computations to compute pseudoabsolute acceleration (PSAA), absolute acceleration (AA), pseudorelative velocity (PSRV), relative velocity (RV), and relative displacement (RD) for 0, 2, 5, 10, and 20 percent critical damping. However, because of the large number of seismograms processed in the present study, we limited our response spectral calculations to five-percent damped PSRV response spectra--those most used by engineers.

PSAA and RD are easily computed from PSRV by applying the simple relationships:

$$\text{PSAA} = 2\pi f \cdot \text{PSRV} \quad (9)$$

$$\text{RD} = \text{PSRV}/2\pi f \quad (10)$$

AA and RV are not so easily computed; however, they can be calculated from the corrected acceleration time series provided on an accompanying magnetic tape by using any number of available algorithms (e.g., Nigam and Jennings, 1969; Converse, 1984).

Plots of the Fourier amplitude and PSRV response spectra for those corrected time series previously selected for plotting are displayed in the Appendix.

## STATISTICS OF PEAK GROUND-MOTION PARAMETERS

Summary statistics for the peak ground-motion parameters computed in this study are presented in Table 5. These statistics show relationships between components (e.g., ratios of vertical components to horizontal components), relationships between parameters (e.g., ratios of peak velocity to peak acceleration), and relationships between various stages of processing (e.g., ratios of corrected peaks to uncorrected peaks) for all of the seismograms processed in this report.

Of particular interest are the statistics summarizing the ratios of SMA-1 simulated acceleration to uncorrected acceleration, and corrected acceleration to uncorrected acceleration, which demonstrate the effect of reducing the high-frequency content of the uncorrected time series by SMA-1 simulation and filtering. Table 5 indicates that the mean ratio of SMA-1 simulated acceleration to uncorrected acceleration is 1.00 (no reduction) for the average of the two horizontal components of peak acceleration and 1.01 (a 1 percent increase) for the vertical components of peak acceleration. Similarly, the mean ratio of corrected acceleration to uncorrected acceleration is 0.99 (a 1 percent reduction) and 0.98 (a 2 percent reduction) for these same components. Although these ratios exhibit relatively large variability, their mean values indicate that, on average, the energy content of the time series for frequencies of 25 Hz and above does not contribute significantly to the amplitudes of peak acceleration.

#### DATA AVAILABILITY

A magnetic tape of the processed records described in this report can be obtained from the National Geophysical Data Center in Boulder, Colorado. All requests should be forwarded to:

National Geophysical Data Center/NOAA  
World Data Center-A for Solid Earth Geophysics  
325 Broadway, Code E/GC1  
Boulder, CO 80303

#### ACKNOWLEDGEMENTS

The record processing described in this report was funded by the U.S. Nuclear Regulatory Commission under the direction of Dr. Andrew Murphy. We wish to thank Chuck Mueller and Linda Haar for making the data available to us. We are especially grateful to Ed Cranswick, who kindly shared many of his computer programs with us and provided invaluable guidance throughout the study.

Note: A = peak corrected acceleration; V = peak corrected velocity; D = peak corrected displacement.

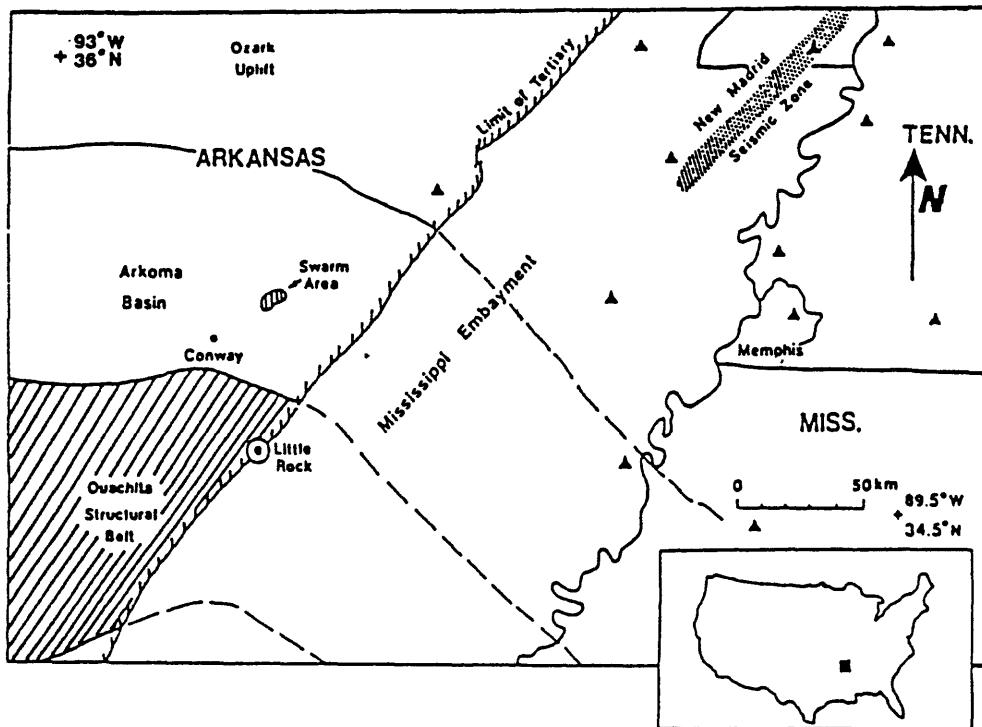

Figure 1. Geographical and geological setting of the Arkansas earthquake swarm (Chiu et al., 1984). Only major geological provinces are shown. The triangles represent permanent seismic stations operated by the Tennessee Earthquake Information Center or Saint Louis University.

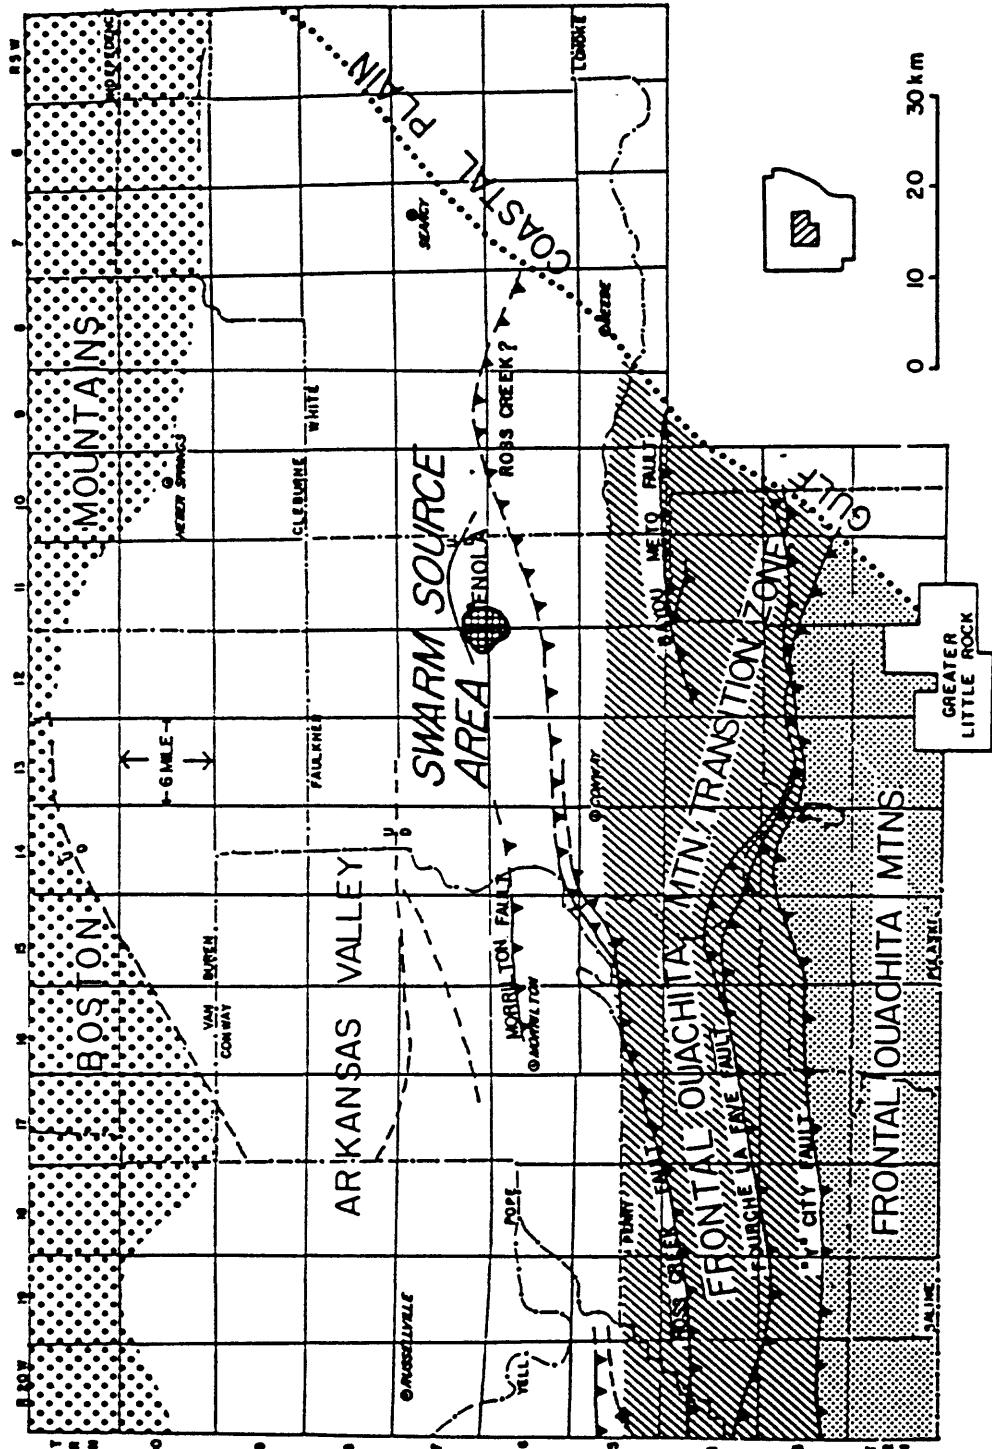

Figure 2. Tectonic/structural setting of the Arkansas earthquake swarm (Chiu et al., 1984; modified from Stone, 1968). The normal fault just north of the swarm area is subsurface, taken from seismic reflection profiles. Faults of the Transition Zone are thrust faults with symbols on the hanging wall.

# FBA

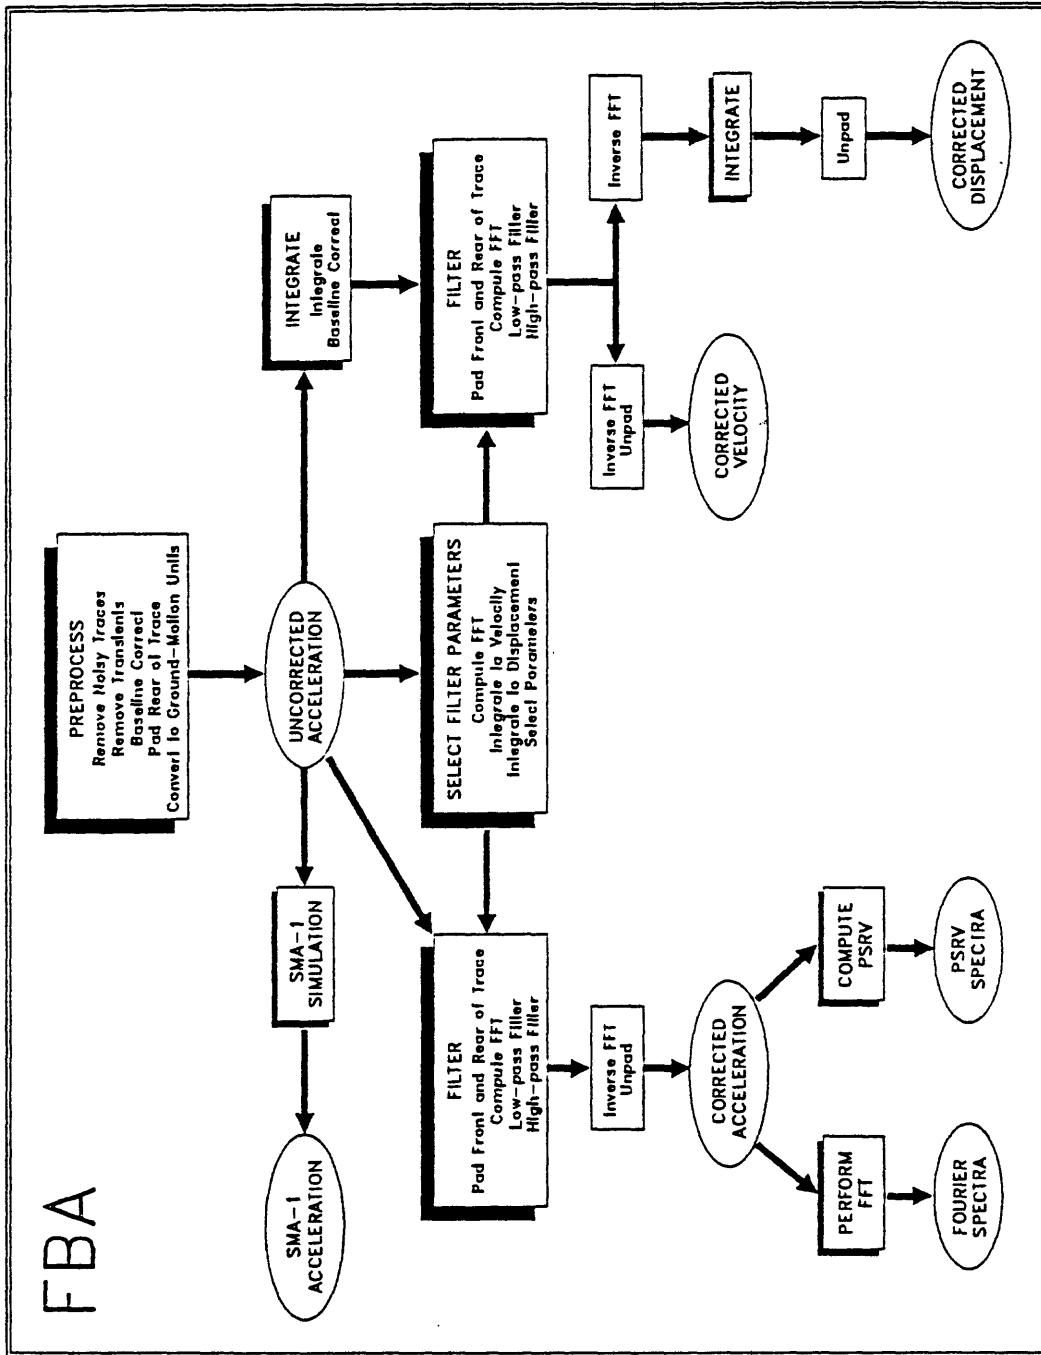

Figure 3. Flowchart showing the computational steps used to process digital FBA recordings of the 1982 Arkansas earthquake swarm.

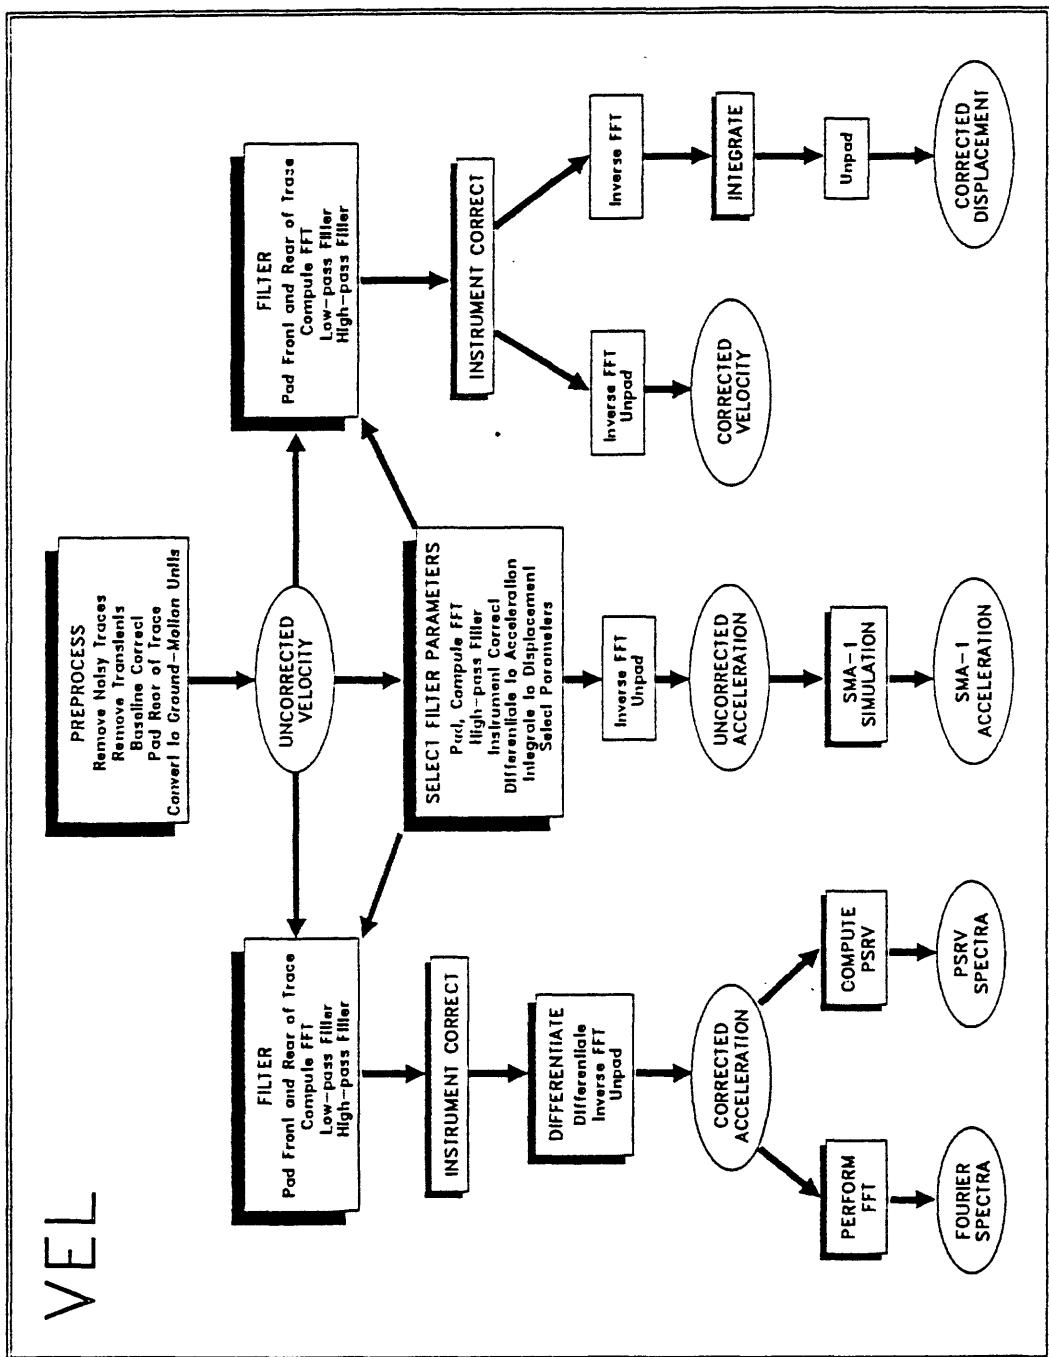

Figure 4. Flowchart showing the computational steps used to process digital velocity recordings of the 1982 Arkansas earthquake swarm.

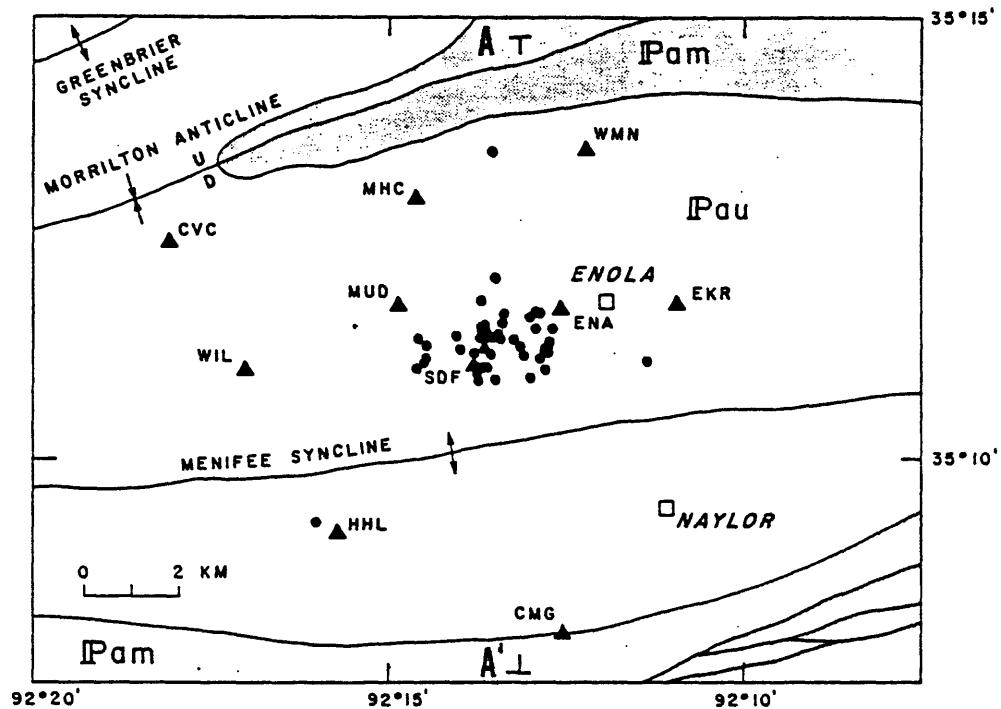

Figure 5. Map of the Enola, Arkansas, area showing locations of the DR-100 digital seismographs (triangles) and located earthquakes (circles) for the period June 24-July 5, 1982 (Haar et al., 1984).

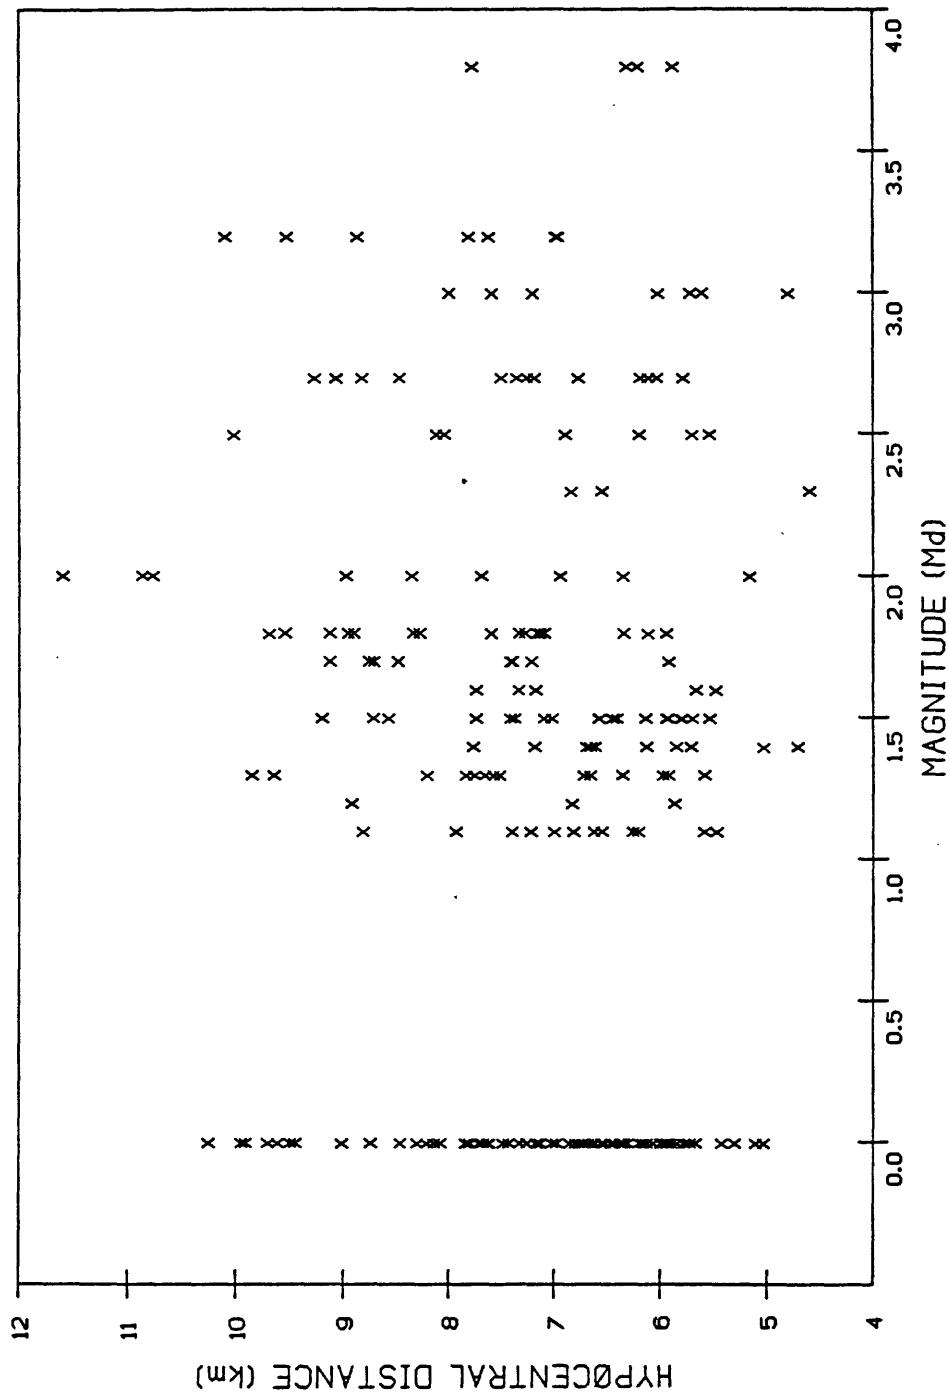

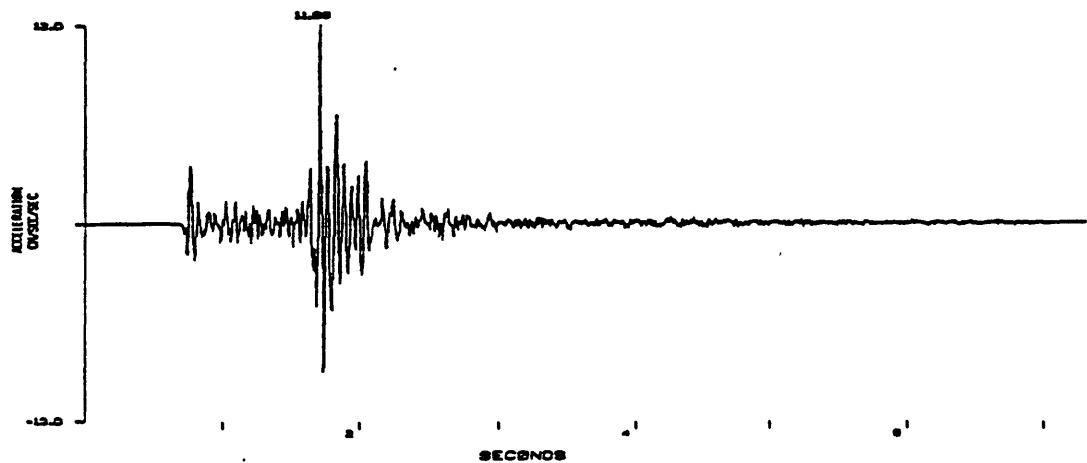

Figure 6. Distribution of processed digital recordings with respect to magnitude and distance for selected earthquakes of the Arkansas earthquake swarm. Unknown magnitudes are assigned a value of zero.
